ABSTRACT. The Waulsortian mudmounds consist of massive limestones that developed from late Tournaisian to early Visean. Secondary dolomitization has locally affected these mudmounds conducting to the coexistence of dolostone and limestone patches. Numerous karst cavities are preferentially developed in dolomitic intervals and are geometrically related to one or several fracture directions. These cavities, called the “dolostone cavity type” can be partially filled with coarse calcite and are usually bounded to the host dolostone by a calcitic transition zone which has a roughly lenticular shape. Petrographic observations, especially under cathodoluminescence, show the following sequence starting from the micro-cavities/micro-fractures network in the transition zone: 1) calcite cement in cavities, 2) dedolomite fabric, 3) host dolomite. The observed microscopic features, as well as morphological data, lead to the development of a conceptual genetic model of karst formation at macro- and microscale. In this model, first a strong dissolution of the host dolostone occurred from the fracture network thereby creating karst cavities (at macroscale) and important pervasive porosity in the host dolomite. Afterwards cementation of the residual porosity and precipitation of coarse calcite in the karst cavities occur. Even if the geological conditions under which these processes took place are not fully unraveled yet, a model that could fit with the data is presented. A discussion about the paleo-environment and paleo-hydrological conditions is settled and we also propose that the development of karst in the dolomitized mudmounds is favored by the coexistence of dolostone and limestone patches given their initial difference in porosity and competence.

KEYWORDS. Waulsort Formation, karstogenesis, dolomite dissolution, calcite replacement, calcite cementation, dedolomite, cavity, dissolution porosity.

1. Introduction

The Waulsortian mudmounds consist of massive limestone buildups outcropping amongst other Carboniferous carbonates in the Dinant area in Belgium. Their description and the study of their sedimentological setting is mainly the work of Lees who concluded that these limestones correspond to lime mud accumulations from a probable microbial origin (Lees, 1982; Lees and Miller, 1995; Lees, 2006). An important dolomitization affected some parts of these buildups. Even if the Waulsortian rocks are prone to karstification, karstic features were never studied.

The present study started with the simple observation that on a regional scale, the Waulsort Formation is statistically more affected by karstification than the other limestone formations nearby. Consequently the question arose: why those partially dolomitized rocks are more prone to karstification than the limestones nearby? Obviously this question relates to difference in relative solubility of limestone and dolostone as well as the structural and mechanical influences on karst development and the paleo-conditions under which karstification took place.

In this paper field observations and laboratory investigations are summarized and the paper aim to demonstrate that a specific karst development took place in the dolomitized sections of the buildups. Dolostone dissolution, dedolomitization and calcitization are the various processes implied in this particular karst formation which are presented in a karst genetic model.

2. Geological and karstic settings

The studied sites are located in Belgium, in the area of Dinant (Fig. 1). Two Waulsortian sites have been studied, especially addressing karst development, namely Furfooz, along the Lesse valley, and Moniat standing in the Meuse valley. The landscape consists of a large undulating plateau area (called “le Condroz”) cut by those two valleys. The maximum altitudes rise around 280 m above sea level and the basellevel is around 100 m. From a geological point of view, the Dinant area represents the front part of a thrust sheet (the Ardenne allochton) limited to the North by the Midi Fault. The Ardenne allochton has been folded and faulted during the Variscan orogeny (Michot, 1980; Meilliez et al., 1991; Vanbrabant, 2001; Lacquement et al., 2005). In Belgium, karst is developed in various Devonian and Carboniferous limestone formations of the Ardenne massif (Van den Broeck et al., 1910). These karst networks are related to the rivers cutting within the Ardenne massif during Late Tertiary to Early Quaternary (Ek, 1976; Quinif, 1989).

Waulsortian limestones buildups started during the late Tournaisian and lasted till the Tournaisian-Visean transition. These strata consist of mudstones and wackestones showing a mono-specific fauna indicating marine settings extending from depths of several hundred meters to relatively shallow, photic environment. They represent local, lenticular mud accumulation several kilometers in length and around 300 meters in thickness. Secondary dolomitization at regional scale has notably affected Several karst networks are related to the rivers cutting within the Ardenne massif during Late Tertiary to Early Quaternary (Ek, 1976; Quinif, 1989).

the Waulsortian rocks conducting to the coexistence of dolostone and limestone patches. According to Miller (1986), dolomitization of the Waulsortian limestones corresponds to the last diagenetic stage following cementation and occurred during deep burial. Buildups pinch out laterally and give way to peri- and post-waulsortian facies called the Bayard, Leffe and Moliignée Facies (Fig. 2A) (Lees et al., 1985; Lees, 1997; Poty et al., 2001). These laterally-equivalent facies are well-stratified in contrast to the mudmounds, which mostly show a crude stratification except for some few well-bedded intervals. These dominantly non-stratified units display a peculiar behavior with respect to tectonic deformation. Therefore, despite that the basement in the study area was mainly structured by Variscan tectonics, folding is not really manifested in the mudmounds (Brodkom, 1994). Folds in the Devono-Carboniferous deposits in the region are oriented West-East and are usually slightly overturned towards the North with strongly dipping beds (Fig. 2B).

3. Field observations

The dolomitized Waulsortian limestones and the peri- and post-Waulsortian facies occur adjacent to various regional limestone deposits. Although the Bayard and Leffe Facies are also dolomitized, the Moliignée and the early Tournaisian formations (Hastiére, Landelies and Maurenne Formations) are pure limestones usually not affected by dolomitization, and they may be argillaceous. Reports on karst occurrence (CWEPSS, 1999) clearly indicate that Waulsortian rocks are more karstified compared to other adjacent Carboniferous limestones (Fig. 2B).

Field observations of the karst development in the Waulsortian buildups allow distinguishing two types of karst features (Fig. 3). First, a subordinate karst occurrences correspond to structurally-controlled, classical caves with large conduits developed along a preferential direction. Secondly, rather small (centimeters to a few meters long) and very frequent cavities are developed preferentially in the dolomitized parts of the mudmounds. This study focuses on this last type of cavities, which is named “the dolostone cavity type”.

The observation of numerous occurrences of “dolostone cavity type” on the field (Fig. 4) allowed unraveling the controlling lithological features associated with these cavities. Two major characteristics were observed. First, karstification is preferentially developed along one or several fractures. Second, although the “dolostone cavity type” is found within dolomitized rocks, a calcitic transition zone outlines almost systematically the boundary of the cavities. This transition zone has an elongated lenticular outer shape with its major axis oriented parallel to the fracture. It consists of coarse crystalline calcite as well as microcrystalline reddish calcite. The coarse crystalline calcite can take the form of large calcite rhombohedra that can reach a decimeter in size and that preferentially line the walls of the cavity and fracture axes. Fig. 5 is a sketch of “the dolostone cavity type” that shows the features associated to its development: fractures geometrically related to the cavities, rhombohedra lining the cavities, calcitic zone surrounding the cavities.

Figure 4. Field occurrences of the “dolostone cavity type” at various scales. (A) Centimetric cavity developed on a microfracture [MF]. Calcite crystals are visible on the walls of the cavity. (B) Metric cavity partially filled with large rhombohedra, the inset on the right shows a zoom on the rhombohedra. (C) Metric cavity related to a fracture [F]. A calcitic transition zone [CTZ] is developed between the cavity and the host dolostone [D]. (D) Moniat site with the inset zooming on the cavities and (E) “Puits des Vaux” in Furfooz are metric to plurimetric cavities showing fracture axis [F] and calcitic transition zone [CTZ].
Structural features of the fractures associated with the “dolostone cavity type” are presented in the stereogram in Fig. 6. Two main fracture groups are visible: a first family, represented by strongly dipping planes (60° to 80°) with a roughly E-W strike, is actually parallel to regional stratification. The second family of fractures can be identified as subvertical diaclases their direction varies around N170E which is roughly perpendicular to the stratification. Brodkom (1994) recognized the same fracture groups and added a third one defined also as diaclase planes with a similar direction (N170E) but a weaker dip (10° to 35°). The plots in the center of the stereogram in Fig. 6 could correspond to this third group. According to Brodkom, these groups of fractures are related to the Variscan orogeny.

4. Laboratory investigations

4.1. Material and methods

One well developed occurrence of the “dolostone cavity type” was chosen based on representativeness, exposure and access conditions. The chosen outcrop is similar to the sketch shown in Fig. 5. Samples were collected along various transects with a coring machine (Fig. 7). Sampling density was usually 2 samples per meter along transects, except near the cavity where it was increased to 4 samples/m.

X-ray fluorescence analyses (XRF) were performed at the Central laboratory of Lhoist industry (Lhoist West Europe Division). However, these analyses were realized randomly and only the basic chemical elements were analyzed (Ca, Mg, Fe, Al, Mn and Si). As the bulk chemical composition of the samples didn’t reveal any useful conclusions within the framework of this paper, the results are not presented here.

Thin sections were made from each drilled core. Prior to sawing, the samples were impregnated in epoxy resin for a few days. After mounting on glass slides, the sections were thinned to 40 µm and left uncovered. The thin sections were first studied with a Leica polarizing microscope. They were then diamond-polished for cathodoluminescence (CL) analysis at the University of Mons, Department of Geology and Applied Geology, using a CITL Mk5 unit operated at 15 kV and 500 µA beam voltage and current, respectively. The distinction between calcite and dolomite under CL, which may be ambiguous based solely on visual appearance of their emission colours, was checked using a CITL COS 8200 optical spectrometer. In our samples, calcite and dolomite were emitting at ca. 600 (yellow) and 645 nm (red), respectively, which is consistent with the published Mn$^{2+}$-activated CL emission for these carbonate minerals (e.g. Marshall, 1988).

4.2. Petrography

Field observations permitted to discriminate three main rock textures implied in the “dolostone cavity type”. Fig. 8 shows core samples representing these three textures: i) porous, grey dolomite, ii) coarse calcite, which can take the form of cleaved rhombohedra, iii) reddish, microcrystalline calcite. The three macroscopic textures were studied under conventional...
microscopy and cathodoluminescence. The latter permitted to
determine that the reddish microcrystalline calcite is most probably
dedolomite.

4.2.1. Microscopic fabric description

a) Dolomite (Fig. 9A)
The porous grey dolostone appears as a massive dolostone
showing a dolospar fabric which consists of planar and non-
planar dolomite. The planar crystals have a subhedral to euhedral
morphology and a size between 50 and 250 µm. They commonly
possess a more or less cloudy center. Anhedral, non-planar
dolomite crystals are somewhat larger (150 to 350 µm) but their
boundaries are not well-defined. The texture is thus close to the
“planar-s hypidiotopic mosaic” described by Sibley and Gregg
(1987). This dolostone relates to a secondary dolomitization of
the Waulsortian mudmounds obliterating the original limestone
texture. Initial porosity of the dolostone is rather high (visual
estimation at ~5%).

b) Calcite in cavities (Fig. 9B,C)
The calcite mentioned here is the one that fills cavities
Corresponding to enlarged fractures and not to an inter-granular
porosity. The cavities are micrometer to centimeter large at
the thin-section scale. Calcite crystals filling them up are subhedral
to euhedral and their size is variable but they can reach a few
centimeters. Under CL, a succession of three calcite phases can be
observed from the wall to the center of the cavities: 1) dull yellow
brown-luminescing calcite with patches of non-luminescing
calcite (“patchy” or “P calcite”), 2) non-luminescing (“NL
calcite”) and 3) zoned calcite (“Z calcite”), in which luminescing
and non-luminescing fringes are alternating. This third phase is
not always present in the succession but may dominate in some
of the largest cavities.

c) Dedolomite (Fig. 10)
The third texture observed consists of a complex dedolomite
fabric. Actually two fabrics can be distinguish. A first dedolomite
-DD I- appears, under CL, as a mixture of calcite and corroded
dolomite crystals (Fig. 10A). Budai et al. (1984) stated that
petrographic evidences for dedolomitization include: 1) corroded
dolomite rhombs edges, 2) partial dolomite rhombs floating in a
calcite matrix and 3) calcite patches within the core of dolomite
rhombs. The fabric shown in Fig. 10 A and A’ reflects these
three features. It can clearly be defined as dedolomite given that
dolomite crystals exhibit both peripheral and internal corrosion.
The calcite intergrown with corroded dolomite is interpreted as
replacement calcite. This replacement calcite is mainly patchy-
blotchy “P” calcite under CL (Fig. 10A’). Another dedolomite
fabric (DD II) can be differentiated and develop as coarser,
euhedral calcite crystals with sharp boundaries and enclosing
dolomite inclusions in their centre (Fig. 10B’). In this dedolomite
fabric, P calcite can still be present and in this case is intergrown

Figure 9. A) Dolomite fabric and calcite-filled micro-cavities under cathodoluminescence. Dolomite exhibits bright red luminescence. Porosity appears
as dark spots (arrows). B) and C) Calcite filling micro-cavities. The calcite succession (patchy [P], non-luminescing [NL] and zoned [Z]) is well
represented in (C) whereas in (B) the Z phase is not observed.

Figure 10. Dedolomite fabrics under cathodoluminescence. Dolomite exhibits bright red luminescence, calcite is yellow-
to-brown or non-luminescing. (A) DD I fabric: Relic rhombs are floating in an intergrown patchy calcite matrix. Patchy
calcite has partially replaced the corroded rhombs. (A’)

dolomite rhomb [DR]. (B) DD II fabric: Euhedral dolomite
crystal. (B’), Detail of euhedral
dolomite with sharp crystal boundaries (represented by the
dashed line). Dolomite relics [DR] are visible in the center
of the crystals.
with the dolomite relics in the center of the crystal. However, the major phases in terms of volume are the NL and Z calcite that seem to have overgrown euhedral dedolomite crystals as if they cemented inter- and intra-granular voids.

d) Relationships between the fabrics and interpretation

The distribution of the three fabrics along a sequence 1) dolomite, 2) dedolomite and 3) calcite, reveals the existence of a petrographic gradient developing along the cavities network. The photomicrograph sequence presented in Fig. 11 shows clearly the three fabrics and their organized relationship.

The corroded dolomite crystals are then entirely or partly dedolomitized through replacement (DD I). The last step consists of calcite cementation (void-filling) in inter- and intra-granular porosity and in the cavity. The petrographic gradient is the end result with [CC] calcite in cavities, [DD] dedolomite, [C] calcite-filled cavity.

DD II is then the result of cementation in the inter- and intra-granular voids of the corrodolite dolomite and could therefore be called dedolomite sensu lato. On the other hand, the fine-grained, patchy-luminescing calcite intergrown with dolomite (DD I) is interpreted here as replacive dedolomitization (dedolomitization s.s.). However, patchy-luminescing calcite is often reported as a first stage calcite cementation. It is thus possible that this calcite is at least partly void-filling and not strictly replacive.

5. Discussion and perspectives

A preliminary karst genetic model based on morphological, petrographic and geochemical data can be proposed (Fig. 13). This model reflects the processes presented in Fig. 12 but at macroscopic scale. At first, dissolution of the initial dolostone took place along the discontinuities represented by the fracture network. Fluids penetrated the rock causing pervasive dissolution that progressed from the fractures into the rock. A heterogeneous highly porous material was created and open cavities developed locally. This porous material can be correlated with dolomite and could therefore be interpreted here as replacive dedolomitization (dedolomitization s.s.). This replacement step is followed by cementation that came probably much later. On the one hand calcite cementation produced fabric DD II when occurring in the inter- and intra-granular voids of the altered dolomite, and on the other hand cement fluids precipitated coarse calcite in cavities, i.e. rhombohedra in the largest one. One must be aware that cementation is not necessarily linked to the timing of the karstification/dissolution. However as cementation profited of the voids created by dissolution and as the calcite cement is a major petrographic feature of the “dolostone cavity type”, the cementation is presented as a step of the karst genetic model in order to explain what is observed today in the field.

The environmental, dynamic and hydrological conditions in which this model could be contextualized have yet to be investigated. Indeed, it is generally accepted that limestone has a higher dissolution rate than dolostone, i.e. 3 to 60 times

...
Figure 13. Proposed genetic model for the development of “dolostone cavity type” karst in Waulsortian mudmounds. (A) Initial dolostone. Here presented with a crude subvertical stratification and a fracture network developed parallel to the stratification. (B) Creation of porosity and cavities [C] by heterogeneous dissolution of the dolostone. Porosity is preferentially developed along fractures. (C) Replacive dedolomitization of the altered dolostone occurs from the porosity development. Creation of the DD I. (D) Final step with cementation fluids precipitating calcite in the residual porosity. Creation of the sensu lato dedolomite and of calcite cement in the cavities. Cement grew as calcite rhombohedra in the largest voids (cavities) but the latter were not completely filled so that residual karstic cavities are observable today. (E) Comparison with field observation (the dedolomite/calcite zone [DD-C] is outlined).

Dedolomitization is commonly reported as related to subaerial exposure of dolostone (Swennen et al., 1982; Friedmann, 1994; Cañaveras et al., 1996; Nader et al., 2003). Beside, other studies have suggested that the process also take place in deep environment, i.e. through burial diagenetic process (Land and Prezbindowski, 1981; Budai et al., 1984; Woronick and Land, 1985). As an important driving mechanism of dolomite dissolution, the presence of dissolved sulphate is often invoked: calcium sulfate-rich fluids deriving from the dissolution of evaporites (mainly gypsum) provide calcium and catalyze dedolomitization reactions (Bischoff, 1994; Raines et al., 1997; Arenas et al., 1999). Evaporitic conditions are known in the Visean geological history in Belgium. Evaporite dissolution and subsequent circulation of sulfate enriched solutions have been reported, essentially in the Dinant Sedimentation Area (Boulvain and Pingot, 2012). However evaporite dissolution is not systematically associated with dedolomitization and another source of calcium needs to be found, as pointed out by other studies (Frank, 1981; Theriault and Hutcheon, 1987; Deike, 1990; Khalaf and Abdal, 1993; Ronchi et al., 2004). In the Waulsortian buildups, the origin of calcium ions responsible for dolomite replacement and for calcite cementation could be explained by the heterogeneity of the initial dolomitization and the resulting coexistence of limestone and dolostone. In addition, rocks are dominated by limestones in the study area. Therefore it is likely that fluids flowing through the mudmounds were initially close to equilibrium with limestone, i.e. saturated with respect to calcite and undersaturated with respect to dolomite. These Ca-rich and Mg-depleted fluids were thus potentially reactive against Waulsortian dolostone and this resulted in dolomite dissolution and calcite precipitation. Changes in fluid chemistry and/or in flow regime must however have existed to explain the prevalence of either dolomite dissolution, dolomite replacement by calcite or calcite cementation.

Finally, the fact that karst occurs preferentially in the dolomitized parts of the mudmounds (see 3.) can be explained by the petrophysical properties of dolostone relative to typical limestones. First, dolostone has in this case higher porosity than limestone. Our petrographic observations have indeed shown that the waulsortian dolostone has a rather high porosity (see 5.2.1). Second, dolostone and limestone have a different response to geomechanical stress. Brodkom (1994) inferred that Waulsortian dolostone bodies acted as massive brittle nuclei during the Variscan orogeny whereas limestone had a more ductile behavior. Dolostone bodies with their higher permeability relative to the surrounding limestone are thus capable of channelizing fluids, which explains their high concentration in alteration and karst features. Likely the connectivity of these bodies at regional scale is an additional important parameter, but the latter remains to be investigated.

Assessing the paleoconditions is a key point in understanding the development of the “dolostone cavity type” karst and it will require the use of advanced techniques, including trace-element and isotope geochemistry, dating and fluid inclusions studies. Future analysis should also include the investigation of other cavities in order to check the consistency of our results at a wider scale and test the genetic model developed so far. Finally, a more detailed structural study has to be carried out in order to link the history of mudmounds fracturing with the development of dedolomitization and karstification processes.

6. Conclusions

Field observations on the locally dolomitized Waulsortian mudmounds lead to the description of specific karst occurrences called “dolostone cavity type”. These karsts are concentrated within dolomitized parts of the mudmounds and exhibit specific features, i.e., the association with one or several fractures and the presence of a calcitic transition zone. The occurrence and origin of the “dolostone cavity type” is probably related to the heterogeneous dolomitization of the Waulsortian rocks where
dolostone bodies acted as permeable pathways due to their high porosity and abundant fractures relative to the host limestone. Field, petrographical and cathodoluminescence analyses reveal that the development of “dolostone cavity type” karsts involves dedolomitization and cementation processes. Fluids first invaded the rock through the fracture network and created a highly porous dolostone material by pervasive dissolution as well as open cavities. Fabric analysis under CL suggests that replacive (“single-step”) dedolomitization has occurred. Furthermore, altered rocks were cemented by calcite precipitation in pores, which can be related to as a two-step dedolomitization process. Calcite fluids cemented as well the cavities, precipitating large calcite crystals in the cavities. These processes are not necessarily linked in time but they are the different steps leading to the actual occurrences of the “dolostone cavity type” and its major features described on the field. The different processes require a change in fluid chemistry and/or flow regime. These changes could have happened in a large range of environments from burial conditions to subaerial exposure.

7. Acknowledgments

The authors would like to thank the Lhoist Central Laboratory for the X-Ray analyses. We are grateful to “Ardenne et Gaume” for the access to the Furfooz Natural Reserve, and in particular to Ch. Goffin, curator of the park. The authors are also grateful to Prof. F. Boulvain and R. Swennen for their critical reviews. This study is part of the first author Ph.D. thesis at the University of Namur.
